A dislocated pisiform: Case report

Earl AD Campbell MD FRCSC, Enzio Magi MD FRCSC

CASE PRESENTATION
A previously healthy 33-year-old orthopedic surgery resident fell while rollerblading, landing on the ulnar and volar side of her outstretched right wrist. On presentation, she had pain and swelling on the ulnar side of her wrist and was unable to extend her wrist. Flexion of the wrist and ulnar deviation of the hand produced pain. She complained of paresthesia in the ulnar nerve distribution of the hand, and on palpation there was a mass present lateral to the hook of the hamate. Roentgenograms of the hand demonstrated a dislocated pisiform bone and a minimally displaced triquetral fracture (Figure 1).

The following day, closed reduction of the pisiform was accomplished under general anesthesia by pushing the pisiform proximally while flexing and pronating the wrist. Her upper limb was then immobilized for three weeks with her wrist pronated, flexed and ulnarly deviated. After three weeks, the splint was shortened to allow pronation and supination, but the wrist was still held flexed and deviated ulnarly for another three weeks. Six weeks postoperatively, the splint was removed and physiotherapy was commenced. Six weeks after removing the splint, x-rays showed that the pisiform bone had maintained its reduced position (Figure 2), and the wrist exhibited a full range of motion with pain only at the extremes of flexion and ulnar deviation. Fifteen months post-injury, the wrist was asymptomatic and the pisiform bone was still adequately reduced (Figure 3).

DISCUSSION
Dislocation of the pisiform bone is a very rare occurrence. To date, there have only been 11 reported cases of isolated pisiform dislocation (1-10), plus an additional three cases of combined hamate and pisiform dislocation (11,12). The anterior aspect of the pisiform is dome shaped and covered with soft tissue attachments including the flexor carpi ulnaris tendon, transverse carpal ligament, abductor digiti minimi, extensor retinaculum, pisometacarpal ligament, pisohamate ligament, pisotriquetral joint capsule and a band extending to the hook of the hamate. Rather than imbedding the pisiform, the flexor carpi ulnaris attaches to the anterior aspect of the pisiform (13). Because the articulation of the pisiform on the hamate is almost flat, the pisiform relies on these soft tissue attachments for its stability. While all of these structures provide support, the flexor carpi ulnaris tendon is the most substantial proximal stabilizer of the pisiform. The normal...
forces of the flexor carpi ulnaris pull the pisiform proximally. Therefore, the lateral structures, including the transverse carpal ligament and anterior carpal ligament, are more developed and stronger than the medial soft tissue attachments (13).

The pisiform bone acts as a lever to increase the force of wrist flexion supplied by the flexor carpi ulnaris. It also distributes the pull of the flexor carpi ulnaris to the pisometacarpal and pisohamate ligaments to aid wrist flexion (13).

The pathogenesis of a dislocated pisiform remains obscure, but there are two probable mechanisms. Direct force applied to the pisiform bone may result in a dislocation. Alternatively, acute dorsiflexion of the wrist with the flexor carpi ulnaris already contracted and the wrist flexed may cause the pisiform bone to become dislocated (6). It is more likely that our patient’s injury was caused by direct force applied to the pisiform bone.

Treatment of a dislocated pisiform can be either surgical or nonsurgical (6). Ozzene (3) and Mather (4) treated dislocation of the pisiform bone by repositioning and immobilizing it. Unfortunately, this procedure produced unsatisfactory results. However, Sharara and Farrar (8) reported a successful closed reduction and attributed this to keeping the wrist pronated and flexed to relieve tension in the flexor carpi ulnaris. Alternatively, Minami et al (6) and Ishizuki et al (7) advocated resection of the pisiform. Each of their patients had an asymptomatic wrist postoperatively. Resection of the pisiform bone is supported by Jenkins (14), who states that the pain will persist if the pisiform is unstable on the triquetrum, and osteoarthritis of the pisotriquetral joint will be a likely sequela with pisotriquetral instability. We performed a closed reduction and immobilization of the pisiform advocated by Sharara and Farrar (8), which produced a satisfactory result.
