Fabrication of silicone tubes in experimental nerve surgery

MM Al-Qattan MB BS FRCSC

There has been a recent interest in ‘biological’ treatment of nerve injuries using silicone tubes. The proximal and distal nerve stumps are enclosed in a silicone tube leaving a short gap between the two stumps. This technique has been used both experimentally (1) and in humans (2). Silicone tubes have also been used to ‘band’ intact nerves experimentally to produce chronic nerve compression (3). This paper describes a technique of fabricating silicone tubes to the desired dimensions from a silicone sheet.

MATERIALS AND METHODS

A silicone sheet (0.005 inch thick, non-reinforced medical grade silicone rubber, Dow Corning, Midland, Michigan) that is commonly used as a subdermal implant is used to fabricate silicone tubes of different dimensions. The fabrication of a 10 mm silicone conduit with an inner diameter of 1.5 mm will be described here because such a conduit is suitable for the rat tibial nerve defect. However, the same technique can be used to fabricate larger or even smaller tubes.

The procedure was done using an operating microscope and a piece of silicone sheet measuring 5 x 10 mm. The tube was fabricated by suturing the two long borders together using multiple interrupted 10-0 nylon sutures. The resulting tube was 10 mm long with an inner diameter of 1.5 mm (Figure 1). The tube was then used to bridge a 6 mm gap of the rat tibial nerve by inserting 2 mm of the proximal and distal stumps into both ends of the tube. The nerve ends were fixed to the tube with two epineural sutures (10-0 nylon).

RESULTS

Fabrication of each silicone tube took about 15 mins. The fabricated tubes did not collapse and successful nerve regeneration across the nerve gap was obtained.

DISCUSSION

When compared with manufactured ‘readymade’ silicone tubes, self-fabricated tubes have two main advantages: lower cost (a single silicone sheet of 30 x 15 cm can be used to fabricate 30 tubes); and fabrication to the desired dimensions is possible without having to order tubes of different sizes. Furthermore, the tube can be fabricated in situ to ‘band’ intact nerves experimentally to produce chronic nerve compression. When ‘readymade’ tubes were used to ‘band’ intact rat sciatic nerves (3), the tube had to be split longitudinally, then slipped around the intact nerve and nylon sutures were then placed into the silastic to close the tube (3).

Disadvantages of self-fabricated tubes include the time taken for fabrication and the need for a 10-0 nylon suture. In order not to waste any time while the animal is anaesthetized, the tubes can be fabricated before anaesthesia. The same 10-0 nylon suture used to fabricate the tube can also be used to suture the nerve ends to the silicone.
