Migration of metallic mercury in the hand

Neil J Wells BSc MD, James C Boyle MD FRCSC, Victor Wood MD FRCPC
Division of Plastic Surgery and Burns, University of British Columbia, Vancouver, British Columbia

Subcutaneous injection of metallic mercury is uncommon and most articles have emphasized the potential systemic complications (1,2). Only a few articles have dealt with the local injury describing it as a foreign body granuloma-type reaction (3,4). This paper reports a case of palmer injection of mercury from a broken thermometer and the unusual local response.

CASE REPORT

A 34-year-old right hand dominant female suffered a puncture wound to the left hand over the base of the thenar eminence. At the time of initial assessment her hand examination was normal except for a small puncture wound at the base of the thenar eminence. At that time, the wound was opened over 1 cm and the visible superficial mercury was removed. There was felt to be residual mercury at a deeper level so a radiograph was obtained which confirmed this (Figure 1).

The patient was referred to a hand surgeon and examined 12 days after the initial injury. The clinical examination was essentially unchanged; however, a repeat radiograph was obtained. This demonstrated the presence of the mercury but it appeared to have spread more proximally and distally compared with the initial radiograph (Figure 2).

The patient underwent surgical removal of the mercury with the aid of fluoroscopy and loupe magnification. Intraoperatively it was noted that the mercury started in close proximity to the superficial palmar arch and extended along the fascia of the first lumbrical. The fascia and mercury were excised en bloc to remove all of the mercury droplets. A follow-up radiograph showed no remaining mercury and the patient has healed without incident.
Wells et al. Migration of metallic mercury in the hand

**Figure 1**) Anteroposterior and lateral radiographs of the patient at the time of injury. Note the larger distal metallic globule.

**Figure 2**) Anteroposterior and lateral radiographs of the same patient 12 days after the initial radiographs. Note the distal fragment has broken up and has started to migrate both proximally and distally, consistent with the intraoperative finding that the mercury was spread along the first lumbrical.
DISCUSSION

The effects of mercury depend on its form and route of absorption. Organic mercury and mercurial salts are not a problem with injection but produce significant effects via oral absorption whereas metallic mercury is poorly absorbed orally, and causes a problem via the cutaneous route. Injury and toxicity as a result of accidental or intentional injection of metallic mercury are uncommon. The effects are caused by the wide distribution throughout all organ systems of the oxidized forms of mercury, and have ranged from a local inflammatory reaction (2,4) to systemic effects on the kidneys, lung and central nervous system (5,6). The history may be unclear in some cases and symptoms may range from local edema to nausea, vomiting, gastrointestinal bleeding, renal failure and neurologic complaints.

The unpredictability of the bodily response and the possibility of these systemic effects led to the early surgical excision in this case. Only at the time of excision, with the observation that the mercury was lying along the fascia of the first lumbrical, was it appreciated that the mercury had migrated along this fascial plane. This migration of the mercury has not been documented before and raises concern regarding the potential spread of the mercury through the fascial planes and sheaths of the hand with the subsequent possibility of diffuse fibrosis.

With the pre-existing knowledge of the systemic risks and now the possibility of a more diffuse local reaction we recommend early complete surgical removal which can be accomplished with the aid of fluoroscopy and loupe magnification.
