CASE REPORT

Refractory Wheezing in Infancy: Congenital Pulmonary Vein Stenosis

Wong JP1,2, Walters JR3, Cuddalore Arivudainambi V4, Venu I5, Etoom Y1,2, Moddie RG1,2, Wong PD1,2*

Congenital Pulmonary Vein Stenosis is a rare condition that presents in infancy with refractory wheezing from pulmonary venous obstruction. It should be considered when more common causes of wheezing have been excluded. Our case, a 6-month-old boy presented with a progressive course. His echocardiogram demonstrated stenosis of the right pulmonary veins which was defined and followed on cardiac computed tomography.

LEARNING OBJECTIVES: Refractory wheezing is recurrent or prolonged wheezing that is difficult to treat and unresponsive to therapy. In infancy, this type of wheezing should elicit investigation for less common causes. Due to the close relationship between the circulatory and respiratory systems, cardiac anomalies should be considered. Our case of congenital pulmonary vein stenosis presented with refractory wheezing from pulmonary venous obstruction. Unfortunately, this disorder has an unrelenting course. Even with early diagnosis and current surgical management, the outcome is poor.

Key Words: Respiratory Sounds; Heart diseases; Pulmonary veins

Abbreviations: CT: Computed Tomography

INTRODUCTION

Wheezing is a high pitched expiratory breath sound. It originates from the narrowing of small bronchial airways or bronchospasm, as commonly seen in asthma or respiratory infections. Less commonly, mucosal swelling, external compression or inhaled foreign body can cause wheezing.

However, due to the close relationship between the circulatory and respiratory systems, wheezing may dominate the clinical picture of congenital cardiac abnormalities. Lesions associated with large left-to-right shunts can cause wheezing, such as the ventricular septal defect or atrioventricular septal defect, or from left ventricular failure and pulmonary venous congestion. Infrequently, wheezing may result from external compression of a vascular ring as it encircles the trachea or lesions with massive cardiomegaly from bronchial compression of a large tense pulmonary artery or distended left atrium. Further, pulmonary venous obstruction from anomalous drainage, cor triatriatum or mitral supravalvular ring and valve stenosis are uncommon causes.

We describe a case of an infant with refractory wheezing from congenital pulmonary vein stenosis. Although rare, congenital pulmonary vein stenosis causing pulmonary venous obstruction should be considered when more common causes, such as bronchiolitis or foreign body aspiration, have been excluded.

CASE REPORT

A 6-month-old boy presented with recurrent wheezing, shortness of breath and respiratory infections. He was first admitted to hospital at 2 months of age after unscheduled office visits for similar symptoms. There was no history of cyanosis, apnoea or foreign body aspiration. Clinical response to salbutamol and fluticasone metered dose inhalers was minimal.

The child’s nasopharyngeal polymerase chain reaction assay for respiratory viruses was negative. His electrocardiogram was normal. His chest radiograph showed interstitial edema predominantly of the right lung and increased vascularity of the left lung. However, pleural effusion was not evident.

His echocardiogram demonstrated moderate to severe stenosis of the upper and lower right pulmonary veins (Figure 1). The left pulmonary veins were unobstructed. There was good biventricular function and no evidence of pulmonary hypertension. Cardiac computed tomography (CT) with contrast confirmed focal stenosis of all right pulmonary veins at the connection to the left atrium with redistribution of pulmonary blood flow to the left lung (Figure 2). Eight months after presentation, cardiac CT revealed progression of stenosis of right upper and lower pulmonary veins (Figure 3) and emphysema of the right middle lobe with long segment narrowing of the right lobar bronchus. After careful consideration, the cardio-surgical team and family chose not to intervene due to the poor results of pulmonary vein stenting and surgery. Currently, the child has no clinical evidence of pulmonary hypertension.

The child’s echocardiogram demonstrated stenosis of the right pulmonary veins. CT with contrast confirmed focal stenosis of all right pulmonary veins at the connection to the left atrium with redistribution of pulmonary blood flow to the left lung.

The severity, number and sidedness of obstructed pulmonary veins dictate the patient’s symptoms. Left sided involvement is worse than right. Most patients present within the first months to years of life with recurrent tachypnea, wheezing and pneumonia. Progressive stenosis results in pulmonary hypertension and edema. Hemoptysis may be prominent.

In young children, echocardiography can provide visualization of the pulmonary veins. Turbulent flow on colour flow doppler or monophasic and increased pulse flow velocity indicate significant obstruction. The pulmonary veins should be thoroughly assessed in all children with congenital heart disease and unexplained pulmonary hypertension. Magnetic resonance imaging and cardiac CT with contrast are useful noninvasive diagnostic techniques. Cardiac angiography provides detailed fluoroscopic visualization of the pulmonary veins while radionuclide quantitative pulmonary flow imaging best evaluates flow distribution (4).

The outcome of congenital pulmonary vein stenosis is guarded. Involvement of all pulmonary veins usually indicates a progressive course with poor long-term survival complicated by pulmonary hypertension, intercurrent respiratory infection or hemoptysis (5). Patients with few pulmonary veins involved have a less severe course. The outcome of surgical repair or stenting remains uniformly poor (6-7). Lung transplantation may be a therapeutic consideration in unrelenting and treatment refractive progression to severe pulmonary hypertension and secondary right heart failure.

ACKNOWLEDGMENT

The authors thank the patient’s family for allowing them to share this case and Ds. SJ. Yoo, J. Coles and M. Abdirrrahman for assistance and review of the manuscript.

DISCUSSION

Congenital pulmonary vein stenosis is a rare condition. It has been postulated to be an abnormal embryological connection in cardiac development of the common pulmonary vein to left atrium (1). Half of patients may have associated cardiac anomalies, including all major malformations. Stenosis may appear as a discrete shelf or diffuse hypoplasia. The latter may not be evident at birth which suggests a pathologic process of cell proliferation and deposition of extracellular matrix (1-3).
