Severe head injury: Prognostic factors and clinical management

Ortega Zufiría JM, Cuba BC, Sierra Rodríguez M, López Ramírez Y, Núñez PP, Degenhardt MT, López Serrano MR, Prieto NL, Dominguez Lubillo C

ABSTRACT

Head injury is a very frequent event, associated with high morbidity rates. Classically, more attention has been paid to severe injury. The aim of this study was to describe a large series of adult patients, older than 14 years, who suffer severe head injury, treated at the University Hospital of Getafe, between 1993 and 2015 (n=86), to study the epidemiological profile, and to analyze the best diagnosis and the treatment carried out, as well as establishing the main prognostic factors that influence the final result. A retrospective study of review of medical records has been carried out, and also hospital consultation. In this study, the variables that have been most determinant of the adverse evolution in the patient suffering from severe head injury are age, size and pupillary reactivity, the worst score obtained by the patient on the Glasgow Coma Scale (GCS) and the lesions found in the Computed Tomography (CT) of the skull. Lesions in severe head injury can be categorized into nine pathological patterns according to the information provided by the CT. These patterns present an anatomical and clinical profile and a well-defined prognostic significance, associated in turn with a behavior pattern of ICP characteristic. Pure extra-axial hematomas are the lesions that present the best prognosis, being the diffuse axonal lesion associated with brain swelling and multiple bilateral contusions which lead to worse evolution. The Rimel Scale correctly adjusts to the severity of head injury. The Glasgow Coma Scale is well related to the final prognosis of the patient with severe head injury.

Key Words: Severe head injury; Intracranial pressure; Coma; Treatment; Prognosis

In industrialized countries, traumatic injuries are the leading cause of death below 45 years, and brain damage decisively contributes to the fatal outcome in more than half of deaths (1). The severity of the trauma is undoubtedly the main determinant of the final evolution. Head injury incidence rates vary greatly according to the countries and epidemiological criteria used, ranging from 50 to 4,500 per 100,000 inhabitants per year (2,3). Considering only those that present brain damage (loss of knowledge, post-traumatic amnesia or others), the average is 200 to 300, per 100,000 inhabitants per year. Of the total of cranial traumas, between 75% and 90% of the cases correspond to mild injury, between 5% and 25% to moderate injury and between 5% and 20% to severe injury, which represents an incidence rate per 100,000 population per year from 150 to 270 for mild injury, from 5 to 60 for the moderate and from 5 to 50 for the severe, respectively (4). The great variability of these figures is explained by the fact that they are decisively influenced by the rules for the inclusion and classification of patients employed in the various works (5). The pathophysiological knowledge of cranial trauma is essential to know the clinical evolution, propose an adequate therapeutic and establish prognostic criteria.

Prognostic factors of head injury

Clinical prognostic factors age and previous pathologies: The prognosis is clearly worse, the higher the patient’s age. Children have a better prognosis, although children under 5 years have more mortality than older children or young adults. The mechanism by which age influences negatively is not well known, although it is obvious that the risk increases with factors such as hypertension, arteriolesclerosis and cardiovascular, renal or pulmonary diseases, processes that are more frequent in the elderly. In addition, focal lesions, which generally entail worse prognosis, are more frequent in the elderly (subdural hematomas secondary to falls or aggressions) than in young people (1,4) (diffuse lesions or epidural hematoma, due to traffic accidents). It is evident that cerebral atrophy and alterations in cerebral elasticity and vessels predispose to this type of lesions in the elderly. However, the existence of neurological factors that influence the final prognosis is considered, which is less favorable after 45 years regardless of the existence of previous pathologies, and especially after 55 years, especially if there are other associated diseases. When we know more information about the neurobiology of aging, this phenomenon can be clarified. With regard to previous medical pathologies, it is necessary to indicate the high risk of developing intracranial complications in patients with anticoagulant therapy or coagulation disorders, who suffer cranial traumatism.

Socioeconomic factors: The IQ prior to the trauma has a clear influence on the final cognitive results, and patients with higher educational, economic or professional levels are more likely to return to work (6). If there is previous emotional instability, there is more risk of suffering psychiatric problems after the injury.

Conscious level scoring obtained by the sick on the Glasgow scale for the coma: The severity of the injury is undoubtedly the main determinant of the final evolution, as well as the duration of the alteration of consciousness (4). In severe cranial injury, patients with scores of 3 and 4 have a significantly higher mortality than those of 7 and 8, showing a great variability those who score 5 and 6, so in this last subgroup more data is needed to establish prognostic predictions. In this section it is necessary to indicate that it is estimated that between 10% and 38% of patients with severe injury present a lucid interval in which the physical examination is normal, and can be considered mild and subsequently deteriorating to coma. Within the parameters assessed by the Glasgow Coma Scale (motor, ocular and verbal response), the motor response is the one with the greatest prognostic capacity and, therefore, the highest reliability (6,7).

Injuries and associated extra cranial complications: Systemic injuries associated with cranial injury are very frequent, and it is estimated that they occur up to 50% of severe injury. Logically, they worsen the prognosis, especially if there is hypotension (in 16% of serious traumas) and hypoxemia (in 37% of them) (8). The thoracic trauma is the systemic lesion that most influences the final evolution of the patient. Excarcinan complications that have a significantly greater influence on the final outcome are hypotension, pneumonia, coagulopathy and septicemia (9).

Causing mechanisms: Abuses have a worse prognosis, due to the high incidence of associated systemic traumatic injuries, and bicycle or motorcycle accidents have, paradoxically, a better prognosis, mainly due to the younger average age of these patients, always considering the use of helmet. In gunshot wounds, the prognosis depends on the caliber, velocity and trajectory of the projectile, the CT findings, the ICP figures and the motivation of the incident (suicides have worse evolution).

Other factors:

A. Pupillary size and reactivity: Mydriasis and lack of pupillary reflexes indicate poor prognosis. Between 90% and 95% of patients without pupillary reflexes have an adverse course, especially if they are elderly. If these reflexes are normal, only 29% die.
B. Oculocephalic and oculovestibular reflexes: If they are absent (data of brain stem injury), between 51% and 95% of patients die, and if they survive, very serious cognitive defects will remain.

Radiological prognostic factors

Computed tomography: The mortality of patients with scores lower than 9 ranges between 5% and 74% (average of 41%), depending on the type of existing injury (6). The worst prognosis is associated, in decreasing order, with subdural hematoma, hemispheric swelling, especially in the elderly, and intracerebral hematomas, especially if they are large or multiple. The deviation of the midline structures also has prognostic value. If it is disproportionate to the volume of the lesion, mortality is 39%, and 75% if it is disproportionate to the volume of the lesion. The cisterns of the base also contribute to establish the final evolution. If they are absent, mortality is 72%, 39% if they are compressed and 22% if they are normal. The compression of the ventricular system and the presence of subarachnoid hemorrhage also worsen the prognosis of the patient suffering from head injury. Finally, it should be remembered that a patient with normal CT can develop intracranial hypertension if there is associated pulmonary trauma (10).

Magnetic resonance: The high sensitivity of Magnetic Resonance (MRI) to detect intraparenchymal lesions makes it a very useful tool in determining the prognosis during recovery of the patient suffering from head trauma, but CT remains the technique of choice during the acute phase, because the exploration with RM lasts a long time, is incompatible with some devices used in ICU, the patient is inaccessible during the examination and, in addition, MRI misdiagnoses subarachnoid hemorrhage.

Physiological prognostic factors

Intracranial pressure: The elevation of the ICP above 20 mmHg is related to poor prognosis. This is a very reliable parameter, along with age, Glasgow scale score and pupillary abnormalities, and is intimately linked to blood pressure figures. In addition, intracranial hypertension causes serious alterations of memory in patients who survive.

Blood flow and cerebral metabolism: Determinations of cerebral blood flow have shown that the presence of hyperemia and/or ischemia are associated with poor prognosis. Studies have also been carried out to quantify the oxygen or glucose consumption index, and the alterations with respect to the normal figures indicate worse evolution.

Evoked potentials: The responses obtained in the evoked potentials have the advantage that they are non-invasive techniques, do not need the collaboration of the patient and are not influenced by the administration of drugs, but although they have a high prognostic reliability, they only value the function of certain pathways and neuronal systems and, in addition, are not available in many centers.

Electroencephalogram: It does not relate well with the final forecast. The deeper the coma, the slower the path, but this is greatly affected by the pharmacological therapy received by the patient.

Laboratory data: In general, they do not have good prognostic reliability (11). Several specific enzymatic markers (creatinine phosphokinase, BB isoenzyme, lactate dehydrogenase and glutamic-oxaloacetic dehydrogenase), catecholamine level (adrenaline and noradrenaline), lactate determination and coagulation studies have been studied. Up to 72% of patients with severe trauma have coagulopathies, which are manifested by prolongation of prothrombin time, activated partial thromboplastin or thrombin, decrease in the number of platelets and the number of fibrinogen, and increase in the level of degradation products of fibrin.

Evolution of head injury

A variety of systems have been used to indicate the evolution of cranial injury, from mortality rates to sophisticated methods of assessing organic and psychological sequelae. Mortality rates are the most used and the most useful, because of their easy determination and because most deaths occur shortly after the injury, and it is not necessary to analyze long periods of time. It is estimated that up to 60% of patients with severe injury die at the accident site. In the hospital setting, the first indices published at the beginning of the XX century gave a 70% mortality rate for severe injury, although the figures range from 50% to 76%, with an average of 40% (5). Considering only mortality, you do not have a real vision of the problem, because many of the patients who survive are severely affected. The residual defects can be physical (contractures, ossifications), neurological (hemiparesis, seizures, amnesia), or psychological (alterations of memory, language, behavior). The recovery process after a cranial trauma is a dynamic phenomenon and it is important to decide when to assess the final result. Most authors establish it 6 months after the injury, although this is not a strict criterion that prevents thinking that a patient can improve beyond that date. The probability of developing intracranial injury is very variable, ranging between 30% and 80% (3,8).

APPRAOCH AND OBJECTIVES

Cranial injury represents one of the main causes of mortality and morbidity in industrialized countries, which constitutes an effort, both at a human and economic level, very important. CT not only shows the extra or intra-axial major lesions at any time of evolution, but it allows to acquire dynamic information about the pathological changes that occur at the intracranial level, either spontaneously or at the request of different medical therapeutic maneuvers or surgical, and can demonstrate certain pathophysiological changes such as cerebral edema and intracranial hypertension. In fact, follow-up with sequential CT and continuous monitoring of Intracranial Pressure provides a knowledge of the intracranial pathophysiology that was unthinkable to have a few years ago, but there are still wide gaps in the understanding of the pathogenesis that limit the development of a therapeutic scheme optimum. In addition, the clinical model of cranial injury is multifactorial, both clinic-pathological terms and treatment, so it is very difficult to determine the effect of a pathological or therapeutic variable on the evolution or the final prognosis of patients. The progress experienced in the management and treatment of patients suffering from severe head injury has allowed a marked improvement in prognosis. Thus, it has been possible to reduce the mortality rate by up to 30%, without increasing the number of patients who remain in a persistent vegetative state or develop severe disability, according to the criteria of the Glasgow Evolutionary Scale, although it is still close to the 40% Currently, it is necessary to determine the most influential factors in the final evolution in order to establish prognostic models and to be able to draw up therapeutic action plans and rehabilitation, as effectively as possible. The Glasgow Scales for Coma and the scale introduced by Rimel et al., Which divides injury into mild, moderate and severe, are universally accepted. The usefulness of these scales, which estimate the severity and prognosis of the injury, has been proven in the patient suffering from severe injury, although they are complemented with the assessment of other parameters. Considering all the previously exposed, this work tries to fulfill the following objectives:

1. To collect a wide range of patients who have suffered severe head injury and study their epidemiological profile and clinical presentation.
2. To verify the usefulness and efficacy of the Glasgow Coma Scale andkelası Scale, in determining the severity and prognosis of cranial injury.
3. To study the evolutionary patterns in severe cranial injury, according to the Jennett and Bond scale, and analyze the different variables that can act on them, determining which have greater significance and designing an initial and late prognostic prediction model.

MATERIAL AND METHODS

Inclusion criteria and classification of patients

Getafe University Hospital is a center that serves a Reference population of 800,000 inhabitants, and traumas have been classified, following the Glasgow Scale for Coma, in mild (patient that obtains 13 to 15 points), moderate (score from 9 to 12) and serious (score from 3 to 8). The chosen moment to apply the scale in the classification of them, has been after 6 hours after the trauma. In those cases in which the patient could not be assessed at 6 hours (sedorelated or anesthetized patients), the best score obtained after nonsurgical resuscitation measures was chosen. The variables analyzed in severe head injury are shown in Table 1.

Diagnosis and clinical management of the patient with cranial injury

Patients admitted with severe injury were received directly in the ICU, where they underwent clinical examination to check and normalize, when necessary, the hemodynamic and respiratory situation, and to discard the existence of associated extracranial lesions. The presence of these lesions can seriously compromise the cardiovascular or respiratory function, sometimes demanding an urgent action, which is carried out according to a previously systematized scheme in our center. When the patient’s condition was stable, a general radiological study and brain CT were performed, usually without intravenous contrast administration. To define the pathological findings on CT, we have used our own classification, which is reflected in Table 1. It should be noted that only a part of the patients could be classified on the basis of the initial CT, while other patients they have been based
on the findings of the control CT. The ICP was monitored in all patients who showed focal lesion or diffuse swelling that made the development of intracranial hypertension probable. The patterns found in the evolution of the ICP are listed in Table 1. Each of these patterns (represented also in a Cartesian form) takes on significance in the retrospective or final study of each case, but in many patients the pattern can be predetermined over the basis of the initial ICP and the type of lesion on CT, which can be very useful for designing therapeutic management. The ICP figures have been measured with an intraventricular catheter in the right frontal horn or lateral ventricle. Within the general therapeutic measures, all associated metabolic or systemic problems and convulsive states were treated, although routine antimicrobial therapy was not used, the coagulopathy was solved if it existed, a respiratory physiotherapy treatment and early rehabilitation was initiated, and provided an adequate nutritional supplement through parenteral nutrition. The management of focal lesions has followed the guidelines set out in the literature.

Table 1
Variables analyzed in severe injury

Statistical study of the sample
The first models were based on evidence based on the Bayes Theorem to calculate the evolution combining several factors, but these tests ignore the interdependence between them. Subsequently, the linear logistic regression was introduced, the most used currently, which assesses the influence of various variables on a previously established model, in general good or bad evolution, making possible the realization of a scale of prognostic factors, and through various mathematical models, a prognostic reliability index. Linear regression allows us to elaborate a classifying model of the various evolutionary indicators. The variables that have been shown to be most useful are, in a decreasing sense, the need for surgical decompression, age, physiological state at admission (presence of hypoxemia, hypercapnia or hypotension, decreased hematocrit), motor response and pupillary response. With these models prognostic reliability has been achieved between 30% and 90%, depending on whether they are used early or late, always considering falsely optimistic forecasts so as not to interfere in the possible therapeutic measures that could be applied to the patient. For the descriptive statistics the most usual parameters have been used, such as means, percentages, standard deviations (s), proportions and others. The final evolution of the patient with cranial injury has been determined at the time of hospital discharge. Within the chapter of analytical statistics, for the bivariate study we have used Chi square tests, Spearman correlation coefficient, Student’s “t”, Wilcoxon tests for independent variables and Kruskal-Wallis, and Fisher’s exact test. The limit of statistical significance has been established in a confidence interval of 95% (p <0.05). The multivariate studies were performed using the linear regression method by maximum likelihood.

RESULTS
A total of 86 patients with severe head injury have been treated. Of these, 35 (40.7%) obtained a score of 8 or 7 (Group 1) on the Glasgow Scale for the Coma after applying non-surgical resuscitation measures, 25 (29.1%) obtained a score of 6 or 5 (Group 2), and 26 (30.2%) have a score of 4 or 3 (Group 3).

Epidemiology and descriptive statistics
The results obtained in the different variables analyzed in the severe cranial injury are presented below.

Age
Among the patients in Group 1, there are 24 (68.6%) under 35, 8 (22.8%) have between 35 and 65, and 3 (8.6%) are over 65 years old. In Group 2 patients, there are 20 (80%) under 35, 4 (16%) between 35 and 65, and 1 (4%) over 65 years. Among patients in Group 3, there are 11 (42.3%) under 35, 13 (50%) between 35 and 65, and 2 (7.7%) over 65 years. The average age is 33.9 years (s = 16.83), ranging in a range between 14 and 83 years.

Sex
In Group 1 there are 27 men (77.1%) and 8 women (22.9%). In Group 2 there are 21 men (84%) and 4 women (16%). In Group 3 there are 21 men (80.8%) and 5 women (19.2%).

Causing mechanisms
(Figure 1): In Group 1, there are 15 vehicle occupants (42.8%), 4 who suffer outrage (11.4%), 7 bicycle or motorcycle accident (20%), 8 fall (22.8%) and 1 direct impact (2.8%). Among the patients of Group 2, 13 are vehicle occupants (52%), 3 suffer from being run over (12%), 4 bicycle or motorcycle accident (16%), 3 fall (12%), 1 direct impact (4%) and in 1 case the cause is unknown (4%). Among the patients of Group 3, there are 9 vehicle occupants (34.6%), 1 suffering from being run over (3.8%), 8 bicycle or motorcycle accidents (30.8%), 4 falling (15.4%), 2 injuries by firearm (7.7%) and in 2 cases the cause is unknown (7.7%).

Origin of the sick
58.1% (50 patients) come directly from the accident site, and 41.9% (36 patients) are transferred from another hospital.

Traumatising-intimate interval: The average delay between injury and hospital admission is 4.4 hours (s=6.73), ranging from 0.2 to 48 hours.

Medical history
82.6% of the patients have no known pathological history, 10 patients (11.6%) have a history of alcohol intake or drug use, 1 patient (1.2%) history of generalized seizures and 4 patients (4.6%) other antecedents.

Associated traumatic injuries
Among the patients in group 1, there are 18 patients with associated injuries (51.4%), with 2 cases of spinal trauma (11.1%), 5 facial injury (27.7%), and 3 thoracic-abdominal traumas (16, 7%), 3 orthopedic injury (16.7%) and 5 traumas (27.7%). In group 2, 11 patients have associated injuries (44%), with 3 cases of facial injury (27.3%),
The results obtained in the different variables analyzed in the initial CT are computed tomography of patients (79.6%), and sunk in 10 (20.4%). (95.3%), with a fracture detected in 49 (59.8%). The fracture is linear in 39 (47.6%), and the others (47.6%) are associated with swelling (25.7%), 2 pure epidural hematoma (5.7%), 3 epidural hematoma with associated swelling (8.6%), 3 pure subdural hematoma (8.6%), 3 subdural hematoma with associated swelling (14.3%), 1 focal contusion (2.8%) and 1 bilateral multiple contusions (2.8%). In Group 2, there is a patient with normal CT (4%), 10 cases of diffuse axonal injury (40%), 6 cases of diffuse cerebral swelling (24%), 2 pure epidural hematomas (8%), 1 subdural hematoma with associated swelling (4%), 1 focal contusion (4%), 2 unilateral multiple contusions (8%) and 2 bilateral multiple contusions (8%). In Group 3, 6 cases of diffuse axonal injury (24%), 3 diffuse axonal injury with associated swelling (12%), 11 of diffuse swelling (44%), 1 pure epidural hematoma (4%), 3 subdural hematomas with associated swelling (12%) and 1 unilateral multiple contusion (4%).

Subarachnoid hemorrhage: In Group 1 there are 18 patients (51.4%) with subarachnoid hemorrhage, 14 (56%) in Group 2, and 16 patients (61.5%) in Group 3. In total, 55.8% of patients have subarachnoid hemorrhage.

Intraventricular hemorrhage: In Group 1 there are 9 patients (25.7%) with intraventricular hemorrhage, 7 (28%) in Group 2, and 14 patients (53.8%) in Group 3. In total, 34.9% of the patients have intraventricular hemorrhage.

Pneumocephalus: In 17 patients (19.8%) the presence of air in the intracranial compartment was observed on CT.

Volume of injuries: The average volume is 27.1 cc. (s = 49.91), oscillating in a range between 0 and 270 cc. The volume is less than 25 cc. In 59 patients (73.7%), between 25 and 50 cc. in 8 (10%), and greater than 50 cc. in 13 patients (16.3%).

Deviation of the middle line: The average deviation is 4.9 mm. (s = 6.93), oscillating in a range between 0 and 26 mm. The deviation of the midline is less than 7 mm. in 56 patients (70%), between 7 and 15 mm. in 13 (16.2%), and greater than 15 mm. in 11 patients (13.8%).

Cisternal system: In Group 1, cranial base cisterns are normal in 14 patients (40%), compressed in 14 (40%), and absent in 7 patients (20%). In Group 2, mesencephalic cisterns are normal in 12 patients (48%) and are compressed in 13 (52%). In Group 3, they are normal in 5 patients (18.9%), appear compressed in 10 (40.5%), and absent in 10 patients (40.5%)

Ventricular system: In Group 1 the ventricles are normal in 14 (40%), and are compressed in 21 (60%). In Group 2, they are normal in 12 (48%), and appear compressed in 13 (52%). In Group 3, they are normal in 5 (19.2%), and are shown compressed in 21 (80.8%).

Medical treatment: Sedo-relaxation is practiced in 86 patients (100%), and hyperventilation in 80 (93.1%). Treatment was established with Mannitol in 37 (43.1%) and with Thiopental in 22 (25.6%).

Surgical treatment: In Group 1, 19 patients were not intervened (54.3%), fracture elevation was performed in 1 patient (5%), surgical debridement in 1 (3%), lobectomy in 3 (15%), decompressive surgery in 3 (15%), burr holes in 4 (20%), and evacuation of the lesion in 8 patients (40%). In Group 2, 15 patients were not operated on (60%), fracture elevation was performed in 3 patients (25%), lobectomy in 4 (33.3%), burr holes in 3 (25%), and evacuation of the injury in 2 (16.7%). In Group 3, 9 patients were not intervened (34.6%), lobectomy was performed in 4 (18.2%), decompressive surgery in 7 (31.8%), burr holes in 2 (22.7%), and evacuation of the lesion in 6 patients (27.3%). In 32 (80%) of the 40 patients operated on (46.5%), 1 intervention was performed, and in 8 (20%), 2 interventions were performed. The average score on the Glasgow Scale for the Coma at the time of surgery is 4.2 (s = 1.44), ranging from 3 to 8.

Monitoring the ICP: The ICP is monitored in 22 patients in Group 1 (62.8%), in 14 in Group 2 (56%), and in 13 patients in Group 3 (50%). In 38 (77.5%) of the 49 patients monitored (56.9%) intraventricular technique is practiced and in 11 (22.5%), intraparenchymal technique (Figure 1). The average duration of monitoring is 7.8 days (s=5.68), ranging from 1 to 23 days. The duration is less than 7 days in 28 patients (57.1%), is comprised between 7 and 14 days in 14 (28.6%), and is greater than 14 days in 7 (14.3%).

Initial ICP: In Group 1, the initial ICP is less than 20 mmHg in 11 patients (50%) and greater than 20 mmHg in 5 (20%). In Group 2, it is less than 20 mmHg in 6 patients (42.8%) and greater than 20 in 8 (57.1%). Among patients in Group 3, it is less than 20 mmHg in 6 (46.1%) and greater than 20 in 7.
Evolution of the ICP: In Group 1, the ICP follows pattern 1 (low) in 6 patients (27.3%), pattern 2 (low/high/low) in 6 (27.3%), pattern 3 (high / low / in 4 (18.2%), pattern 4 (low/high) in 1 (4.5%), pattern 5 (high / low / high) in 1 (4.5%), and pattern 6 (elevated) in 4 patients (18.2%). Among patients in Group 2, the ICP follows pattern 1 in 6 (46.1%), pattern 2 in 2 (15.4%), pattern 3 in 3 (23.1%), pattern 4 in 1 (7.6%), and pattern 6 in 1 patient (7.6%). In Group 3, the ICP follows pattern 1 in 4 (30.8%), pattern 2 in 2 (15.4%), and 5 days (32.1%), pattern 4 in 2 (15.4%), and pattern 6 in 2 patients (15.4%) (Figure 2).

ICP more representative: In Group 1, the most representative ICP is less than 20 mmHg in 8 patients (36.4%) and greater than 20 in 18 (63.6%). In Group 2, the most representative ICP is less than 20 mmHg in 7 patients (50%) and greater than 20 in 7 (50%). In Group 3, the most representative ICP is less than 20 mmHg in 5 patients (38.5%) and greater than 20 in 8 patients (61.5%).

Clinical deterioration: Clinical deterioration occurs in 18 patients of Group 1 (51.4%), in 3 of Group 2 (12%), and in 2 patients of Group 3 (7.7%). The cause of clinical deterioration in Group 1 is elevated ICP in 4 patients (22.2%), increased hematoma in 4 (22.2%), appearance of new hematoma in 3 (16.7%), infection neurological in 1 (4.5%), and systemic causes in 6 (33.3%). In Group 2, the cause of the deterioration is the increase in hematoma in 2 (66.7%), and systemic problems in 1 (33.3%). Among patients in Group 3, the origin of the deterioration is increased hematoma in 1 (50%), and systemic causes in 1 (50%). The mean delay between injury and clinical deterioration is 23.4 hours (s = 42.36), ranging from 1 to 192 hours. The average score on the Glasgow Scale for the Coma at the time of deterioration is 4.1 (s = 1.41), range: 3-5.

Findings on control CT: In Group 1, the control CT shows improvement in 8 patients (21.6%) and does not show variations in 4 (10.8%). Diffuse cerebral swelling appears in 7 (18.9%), epidural hematoma in 1 (2.7%), subdural hematoma in 1 (2.7%), focal contusion in 6 (15.4%), multiple contusions in 4 (10.8%), other injuries (infection, subarachnoid or other hemorrhage) in 8 patients (21.6%). In Group 2, the control CT is better in 5 patients (20%), and does not show variations in 8 (32%). Diffuse cerebral swelling appears in 2 (8%), epidural hematoma in 1 (4%), focal contusion in 2 (8%), and multiple contusions in 7 patients (28%). In Group 3, the control CT improved in 3 patients (16.7%), and did not show variations in 2 (11.1%). Diffuse cerebral swelling appears in 3 (16.7%), epidural hematoma in 2 (11.1%), focal contusion in 2 (11.1%), multiple contusions in 3 (16.7%), and other lesions in 3 patients (16.7%). Control CT was performed in 76 patients, and there was worsening in 46 (60.5%). The control CT is performed on average at 2.1 days (s = 0.38), ranging in a range between 1 and 7 days. The average number of control CTs is 3.1 (s = 1.49), ranging from 1 to 7.

Evolution to hospital discharge: In Group 1, there are 1 patient who presents severe disability (15.4%), 9 who develop moderate disability (33.3%), 2 with good recovery (6.7%), 7 severe disability (20%), 4 persistent vegetative state (13.3%), 2 die (6.7%). In Group 2, 3 patients presented moderate disability (12%), 7 severe disability (28%), 4 persistent vegetative state (16%) and 11 died (44%). In Group 3, there are 1 patient with moderate disability (3.8%), 1 severe disability (3.8%), 5 persistent vegetative state (19.2%) and 19 who die (73.1%). Of the total number of patients who die, 10 (22.7%) do so within 44%. In Group 2, there are 1 patient with moderate disability (6.7%), 4 severe disability (8%), 5 persistent vegetative state (25%), 1 die (4.8%). Among patients younger than 35 years old, there are 1 presented diffuse axonal injury (16.7%), 2 epidural hematoma (66.7%) and 1 subdural hematoma (16.7%). Age is significantly related to the final evolution (p <0.001). Among patients younger than 35 years old, there is 1 with good recovery (1%), 12 who develop moderate disability (20%), 13 severe disability (23.6%), 8 remain in a persistent vegetative state (14.5%) and 22 die (40%). In the group of patients between the ages of 35 and 65, 2 develop moderate disability (8%), 2 severe disability (8%), 5 remain in a persistent vegetative state (20%) and 16 die (64%). The 6 patients over 65 years of age die (100%).

The causative mechanisms and findings on CT are significantly correlated (p <0.01). Among vehicle occupants there are 2 with normal CT (5.5%), 12 with diffuse axonal injury (33.3%), 1 with diffuse axonal injury and associated brain swelling (3.8%), 5 diffuse cerebral swelling (42.1%), and 5 with epidural hematoma (13.9%), 2 with subdural hematoma (5.5%), 1 with unilateral multiple contusion (2.8%) and 2 with multiple bilateral contusions (5.5%). Of the patients who suffer traumas, 4 have diffuse axonal injury (50%), 1 epidural hematoma (12.5%), 2 subdural hematoma (25%), and 1 focal contusion (12.5%). Among patients suffering bicycle or motorcycle accident, 9 have diffuse axonal injury (47.4%), 1 diffuse axonal injury with associated brain swelling (5.3%), 8 diffuse cerebral swelling (42.1%) and 3 epidural hematoma (15.4%). Among patients who suffer direct impact, 1 has diffuse cerebral swelling (50%) and 1 has subdural hematoma (50%). The mechanisms causing the trauma correlate significantly with evolution (p <0.001). Of the vehicle occupants, 6 develop moderate disability (16.2%), 6 severe disability (16.2%), 10 remain in a persistent vegetative state (27.1%) and 15 die (40.5%). Of the patients who suffer a stroke, 1 develops moderate disability (12.5%), 2 remain in a persistent vegetative state (25%) and 5 die (62.5%).

Among patients suffering bicycle or motorcycle accident, 1 case of good recovery (5.3%), 4 moderate disabilities (21.1%), 7 severe disabilities (36.8%) and 7 deaths (36.8%). Of the patients suffering fall, 2 develop moderate disability (15.4%), 2 severe disability (13.3%), 1 remains in a persistent vegetative state (6.7%) and 10 die (66.7%). Among patients who suffer direct impact, 2 die (100%), and 2 with firearm injuries also die (100%). The lesion volume, the deviation of the cerebral midline and the compression of the cisternal and ventricular systems are related to the most representative ICP figures (p <0.05). The higher the volume of injury, deviation or compression, the higher the figures of more representative ICP. The findings in the initial CT correlate significantly with the findings in the control CT (p <0.001).
The 2 initially normal CT patients show normal controls (100%). Of the patients with initial diffuse axonal injury, 12 show unchanged controls (50%), diffuse cerebral swelling (4.2%), epidural hematoma (8.4%), 3 multiple contusions (12%, 6%), in 2 (8.4%) other lesions appear (infarction, subarachnoid hemorrhage or others) and in 4 patients the control shows improvement (16%). Among patients with diffuse axonal injury and in the control associated brain swelling, there is 1 control that shows improvement (100%). Of the patients with initial diffuse cerebral swelling, 7 did not show changes in controls (20.6%), 3 presented epidural hematoma (8.8%), 4 focal contusion (11.7%), 7 multiple contusions (20%, 6%), 9 have other lesions (26.5%) and in 4 patients the control shows improvement (11.8%). Of the patients with subdural hematoma, 12 die (19.4%), 1 remains in a persistent vegetative state (11.1%), 1 in a 1 focal contusion (11.1%), 1 in 2 brain multiple multiparous (22.2%), in 1 other lesions (11.1%), and in 3 patients the control showed improvement (33.3%). In patients with initial subdural hematoma, 1 control shows significant remains of the hematoma (6.7%), 2 diffuse cerebral swelling (13.3%), 1 focal contusion (6.7%), 4 multiple contusions (26.7%), 4 other injuries (26.3%) and in 3 the control shows improvement (20%).

Of the patients with initial focal contusion, 1 control shows increase in its size (33.3%), 1 unilateral multiple contusions (33.3%) and 1 other lesion (6.7%) and 1 control shows decrease (16.7%) who have control, no variations appear (100%). Of the patients with initial bilateral multiple contusion, 1 control showed associated brain swelling (20%), 3 showed an increase in the size of the contusions (60%) and 1 other lesion (20%). The presence of peritraumatic hypotension correlates significantly with evolution (p < 0.01). Among the patients who have hypotension upon admission, 9 die (69.2%), 2 remain in a persistent vegetative state (15.4%), 6 attend a severe disability (46.2%) and 3 moderate disability (23.1%). Among the patients without hypotemia, 33 died (45.8%), 11 remain in a persistent vegetative state (15.7%), 15 develop severe disability (21.4%), 11 moderate disability (15.7%) and 1 presents good recovery (1.3%). The types of injuries in the initial CT are significantly related to the pattern of behavior of the ICP and to evolution (p < 0.001). Of the patients with normal CT there are 2 who develop moderate disability (100%). Among those with diffuse axonal injury, 8 die (32%), 6 remain in a persistent vegetative state (24%), 7 develop severe disability (28%), 3 moderate disability (12%) and 1 have good recovery (4%). The 4 patients with diffuse axonal injury and associated brain swelling die (100%). Of the patients with diffuse cerebral swelling, 15 died (57.7%), 5 remain in a persistent vegetative state (19.2%), 4 develop severe disability (15.4%) and 2 moderate disability (7.7%).

Of the patients with epidural hematoma, 4 die (36.4%), 1 is left in a persistent vegetative state (9.1%), 3 develop severe disability (27.3%) and 3 moderate disability (27.3%). Among patients with subdural hematoma, 19 die (65.5%), 4 remain in a persistent vegetative state (13.8%), 2 develop severe disability (6.9%) and 4 moderate disability (13.8%). Of the patients with pure extra-axial hematoma, 6 developed moderate disability (85.7%) and 1 severe disability (14.3%). Among patients with focal contusion, 4 died (57.1%) and 3 remain in a persistent vegetative state (42.9%). Of the patients with unilateral multiple contusion, 4 die (66.7%), 1 remain in a persistent vegetative state (16.7%) and 1 develop severe disability (16.7%). The 10 patients with bilateral multiple contusion die (100%). The presence of subarachnoid or intraventricular hemorrhage correlates significantly with evolution (p < 0.01). Of the patients with subarachnoid hemorrhage, 30 die (62.5%), 7 remain in a persistent vegetative state (14.6%), 8 develop severe disability (16.7%) and 3 moderate disability (6.3%). Of the patients with subarachnoid hemorrhage, 12 die (33.3%), 6 remain in a persistent vegetative state (16.7%), 7 develop severe disability (19.4%), 10 moderate disability (27.8%) and 1 has good recovery (2.8%). Among patients with intraventricular hemorrhage, 20 die (66.7%), 6 remain in a persistent vegetative state (20%), 3 develop severe disability (10%) and 1 moderate disability (3.3%). Of the patients without intraventricular hemorrhage, 22 die (40.7%), 7 remain in a persistent vegetative state (12.9%), 12 develop severe disability (22.2%), 11 moderate disability (22.2%) and 1 presents good recovery (1.8%).

The volume of lesions correlates significantly with evolution (p < 0.01). Of the patients with lesions smaller than 25 cc., 27 die (46.5%), 10 remain in a persistent vegetative state (17.2%), 11 develop severe disability (18.9%), 9 moderate disability (15%, 5%) and 1 has good recovery (1.7%). In the group of patients with lesions between 25 and 50 cc., 4 die (44.4%), 2 remain in a persistent vegetative state (22.2%), 1 develop severe disability (11.1%) and 2 moderate disability (22.2%). Of patients with lesions larger than 50 cc., 8 die (61.5%), 1 remains in a persistent vegetative state, 1 moderate disability (15.4%) and 2 moderate disability (15.4%). The deviation of the midline correlates significantly with evolution (p < 0.01). Among patients with deviation less than 7 mm, 24 die (42.8%), 10 remain in a persistent vegetative state (17.8%), 11 develop severe disability (19.6%), 10 moderate disability (17%, 8%) and 1 has good recovery (1.8%). Of the patients with deviation between 7 and 14 mm, 7 die (53.8%), 8 remain in a persistent vegetative state (15.4%), 3 develop severe disability (23.1%) and 1 moderate disability (7.8%).

Of the patients with deviation greater than 14 mm, 8 die (72.7%), 1 remains in a persistent vegetative state (9.1%) and 2 develop moderate disability (18.2%) and ventricular is also related to evolution (p < 0.01). Of the patients with normal cisterns, 10 die (31.2%), 7 remain in a persistent vegetative state (21.9%), 7 develop severe disability (21.9%) and 1 has good recovery (3.1%). Among patients with compressed cisterns, 22 die (66.7%), 3 remain in a persistent vegetative state (9.1%), 4 develop severe disability (12%) and 1 moderate disability (3.1%) and 1 severe disability (11.5%) and 2 moderate disability (7.7%). Among patients with normal ventricles, 9 die (29.1%), 7 remain in a persistent vegetative state (22.6%), 7 develop severe disability (22.6%), 7 moderate disability (22.6%) and 1 presents good recovery (3.2%). Among patients with compressed ventricles, 16 die (51.6%), 6 remain in a persistent vegetative state (18.2%), 12 develop severe disability (36.4%) and 2 moderate disability (9.1%). Of the patients who do not need it, 33 die (51.6%), 9 remain in a persistent vegetative state (14.1%), 10 develop severe disability (30%) and 7 moderate disability (9.1%). The need for barbiturate treatment is significantly related to evolution (p < 0.01). Of the patients requiring Thiopental, 11 die (50%), 4 remain in a persistent vegetative state (18.2%), 5 develop severe disability (22.7%) and 2 moderate disability (9.1%). Of the patients who do not need it, 33 die (51.6%), 9 remain in a persistent vegetative state (14.1%), 10 develop severe disability (30%) and 7 moderate disability (9.1%). The need for surgical treatment is related to evolution (p < 0.05). The need for surgery leads to a worse prognosis. The worst score obtained by the patient in the GCS correlates with the evolution (p < 0.001), and the best score is also related (p < 0.01). The figures of initial ICP and evolution correlate significantly (p < 0.01). Of the patients with initial ICP less than 20 mmHg, 10 die (43.5%), 4 remain in a persistent vegetative state (17.4%), 5 develop severe disability (21.7%) and 4 moderate disability (17.4%). Among patients with initial ICP greater than 20, 14 die (56%), 5 remain in a persistent vegetative state (18.2%), 5 develop severe disability (20%) and 2 moderate disability (9.1%). Of the patients who do not need it, 33 die (51.6%), 9 remain in a persistent vegetative state (14.1%), 10 develop severe disability (30%) and 7 moderate disability (9.1%). The need for barbiturate treatment is significantly related to evolution (p < 0.01). Of the patients requiring Thiopental, 11 die (50%), 4 remain in a persistent vegetative state (18.2%), 5 develop severe disability (22.7%) and 2 moderate disability (9.1%). Of the patients who do not need it, 33 die (51.6%), 9 remain in a persistent vegetative state (14.1%), 10 develop severe disability (30%) and 7 moderate disability (9.1%). The need for surgical treatment is related to evolution (p < 0.05).

Severe head injury: Prognostic factors and clinical management

Neurosurg J Vol 1 No 1 October 2018
Severe head injury: Prognostic factors and clinical management

(18.7%). The duration of coma is related to evolution (p <0.001). Among patients in whom the coma lasts less than 8 days, 25 die (85.3%), 4 develop moderate disability (13.3%) and 1 has good recovery (3.3%). Of which the duration comprises between 8 and 14 days, 9 die (47.4%), 1 remains in a persistent vegetative state (5.3%), 4 develop severe disability (21.1%) and 5 moderate disability (26.3%). Of which the duration is greater than 14 days, 7 die (20%), 13 remain in a persistent vegetative state (37.1%), 11 develop severe disability (31.4%) and 4 moderate disability (11.4%). The findings in the control CT correlate with evolution (p <0.001). Of the patients with normal control CT, 2 develop moderate disability (100%). Among the patients whose control does not show variations, 3 die (21.4%), 5 remain in a persistent vegetative state (35.7%), 5 develop severe disability (37.5%) and 1 moderate disability (7.1%).

Of the patients whose control CT shows improvement, 5 die (31.2%), 1 remain in a persistent vegetative state (6.2%), 4 develop severe disability (25%), 5 moderate disability (31.2%) and 1 has good recovery (6.2%). Among the patients in whose control CT diffuse cerebral swelling appears, 8 die (66.6%), 1 remains in a persistent vegetative state (8.3%), 2 develop severe disability (16.7%) and 1 has moderate disability (8.3%). Of patients in whose control epidural hematoma appears, 1 remains in a persistent vegetative state (33.3%), 1 develops severe disability (33.3%) and 1 moderate disability (33.3%). In the patients in whose control subdural hematoma appears, 1 dies (100%). Of patients in whose control focal contusion appears, 1 dies (16.7%), 2 remain in a persistent vegetative state (33.3%), 2 develop severe disability (33.3%) and 1 moderate disability (16.7%). Of the patients in whose control multiple contusion appears, 8 die (61.5%), 3 remain in a persistent vegetative state (23.1%), 1 develop severe disability (7.7%) and 1 moderate disability (7.7%). Among the patients in whose control other lesions appear (subarachnoid hemorrhage, cerebral infarction or others), 2 die (66.6%) and 1 remain in a persistent vegetative state (33.3%).

**DISCUSSION**

Epidemiological and clinical profile

Recognizing that trauma is currently the main cause of death in people under 45 years of age, and that 50% to 75% of accident deaths are due to head injury, has led to the acceptance that the Cranial nerve represents a public health problem of the first magnitude (11). Efforts to reduce mortality have obviously focused on severe injury, where, despite new diagnostic techniques (CT and MRI) and monitoring of Intracranial Pressure, and advances in treatment, there has been no achieved a great decrease in morbidity and mortality rates, mainly due to the fact that the prognosis is closely linked to the brain damage that the patient already presents at the time of care (12). In studies carried out during the last two decades, only clinical prognostic estimation during the acute phase of severe head injury is of great importance. In studies carried out during the last two decades, only clinical prognostic estimation during the acute phase of severe head injury is of great importance. In studies carried out during the last two decades, only clinical data easy to obtain and applicable in any center were considered. In more recent works, other data or diagnostic and therapeutic parameters with more or less prognostic influence have been incorporated. Different authors have tried to develop a method to calculate the probability of a certain evolution occurring, describing the advantages and disadvantages of the various statistical techniques. However, the information provided in most of these studies, although of undeniable value, is difficult to apply in practice when considering a specific patient. Therefore, it seems essential to establish a statistical method that is reliable and easy to apply (12). This method should use a group of really useful prognostic indicators that have little variability among different observers, and will have to demonstrate real validity after being tested or applied to a wide range of patients.

To design a system like the one indicated, it is necessary first of all to purify the parameters or variables with true prognostic significance, since not all of them have a clearly significant influence on the final evolution. Among the findings collected in the initial CT, the collapse of the mesencephalic cisterns and the deviation of the midline, both radiological indices of transtentorial herniation, are associated with elevated ICP and poor final prognosis. Patients with normal or pathological CT, but without alterations of the midline or deviations of the midline, present normal or moderate elevated ICP and easily controllable, and have a better final evolution. The prognostic value of the status of mesencephalic cisterns has been repeatedly indicated in several studies, and has sometimes been the finding with the

1. There is no pathology visible on CT.
2. Pure diffuse axonal injury with patent cisterns, deviation of the midline less than 5 mm, And / or focal lesions of volume less than 25 cc.
3. Diffuse axonal lesion plus swelling associated with compressed or absent cisterns, deviation of the midline less than 5 mm. and focal lesions of volume less than 25 cc.
4. Diffuse axonal lesion with associated swelling, deviation of the median line greater than 5 mm. and focal lesions of volume less than 25 cc. There is a direct relationship between these four categories and the mortality rate. When used in conjunction with the rest of the CT patterns (extra-axial epi or subdural hematoma, contusions or others), the prognostic reliability increases relative to the probability of developing intracranial hypertension with adverse evolution, and the therapeutic decision is facilitated.

The medical and surgical treatment has followed the global guidelines currently collected in the literature (16). The classification of the behavior of the ICP in 6 well-defined patterns is very useful at the time of deciding the establishment of a specific therapy, and very guiding of the final prognosis of the patient. The values of initial ICP and most representative ICP have less significance with respect to the final evolution of the patient, but represent correct indicators in the clinical and therapeutic management. The incidence of worsening of the control CT is very high, which shows its importance when planning the treatment of the patient who suffers serious injury and confirms the severity of the traumatums collected in our series. This is also verified by the high incidence of pupillary changes and the average of the worst score obtained by the patient in the Glasgow Scale, which is 4.4. As has been demonstrated in previous publications and is evident in the present series, these two parameters considered in isolation have a remarkable prognostic and definitive value of the final evolution of the patient suffering from severe head injury (16).

**Prognostic factors**

The mortality of the serious cranial injury is high, although we must consider that 22% of the patients die in the first 24 hours (6,12). In fact, due to the broad inclusion criteria of patients used in this study, all those with necessarily fatal injuries or whose chances of survival are very remote have been admitted. In the work of the “North American Data Bank” a mortality of 36% is collected, ranging from 76% in patients with a score of 3 in the Glasgow Coma Scale, and 18% in patients who obtain 8 or 7 points. Among patients with diffuse lesions (general mortality of 31%) the prognosis is worse in patients with diffuse axonal injury type III and IV, as compared to the same discussed above among patients with focal lesions, mortality is 39%. As already mentioned in the Introduction chapter, prognostic estimation during the acute phase of severe head injury is of great importance. In studies carried out during the last two decades, only clinical data easy to obtain and applicable in any center were considered. In more recent works, other data or diagnostic and therapeutic parameters with more or less prognostic influence have been incorporated. Different authors have tried to develop a method to calculate the probability of a certain evolution occurring, describing the advantages and disadvantages of the various statistical techniques. However, the information provided in most of these studies, although of undeniable value, is difficult to apply in practice when considering a specific patient. Therefore, it seems essential to establish a statistical method that is reliable and easy to apply (17). This method should use a group of really useful prognostic indicators that have little variability among different observers, and will have to demonstrate real validity after being tested or applied to a wide range of patients.
greatest value in predicting the final evolution; in fact, some authors show that, with the exception of patients who do not brace or do not have any response after the initial resuscitation measures, the degree of collapse of the cisterns is revealed as the most decisive and independent prognostic factor in the first hours after the injury, and conclude that if the cisterns appear collapsed on the first CT, the final outcome tends to be much less favorable than if they are patent or show no distortion, especially in patients who score between 6 and 8 in the Glasgow scale. The results of our study are similar and confirm that the risk of death in patients with severe head injury is greater if there is a collapse of the mesencephalic cisterns. We also found that the pathology or type of lesion causing the cisternal collapse does not influence the aforementioned correlation. Likewise, we observed that the risk of elevation of ICP in patients with abnormal cisterns is three times higher than in patients with normal cisterns. In some publications it has been pointed out that there is no significant correlation between the displacement of the cerebral midline and the levels of ICP (17).

However, we have found that the deviation of the midline in the CT is an indicator of elevation of the ICP, and that there is an important correlation between the degree of displacement and the final evolution, independently of the underlying pathology that causes said deviation. Ventricular asymmetry has been considered by some authors as an unreliable parameter to assess the amount of brain shift. In severe trauma the reduction of ventricular size or its asymmetry are related to elevation of the ICP and worse prognosis, as occurred in other studies. This discrepancy may be due to the difficulty of adequately assessing the ventricular size, and to the variations of the moment in which said estimation is carried out, which may refer to the initial CT after admission or to the subsequent control CT. In our series, it is proven that such deviation associated with hemorrhage is associated with worse evolution when it is not combined with intracranial hypertension. In this regard, it has been speculated whether the mechanism by which traumatic subarachnoid hemorrhage leads to a worse final prognosis is the same as that which operates in patients with aneurysmal rupture. The incidence of vasospasm in severe cranial injury ranges from 5% to 30% in different studies. In studies based on transcranial Doppler examination to determine the presence of vasospasm, an incidence close to 40% is recorded, being observed that it occurs mainly in patients with a large accumulation of blood in the basal cisterns. The authors consider that the incidence of vasospasm in traumatic aneurysmal subarachnoid hemorrhage is superimposable, suggesting that the pathophysiology of the same is similar in both pathological circumstances (18,19).

Other CT data, such as the presence of intraventricular hemorrhage or large volume in the case of focal lesions, are also associated with worse prognosis in the final evolution. The grouping of patients based on the nine patterns of intracranial lesion collected in the CT, has not achieved prognostic significance. The patterns with worse evolution are diffuse axonal injury associated with brain swelling and bilateral multiple contusions. The poor prognosis in patients with multiple unilateral or bilateral contusion is linked to the development of medically intractable intracranial hypertension. In the case of extra-axial hematomas, the CT immediately after the surgery of the hematoma is the parameter that best indicates the possible uncontrollable elevation of the ICP, and the fatal prognosis. The type of hematoma has been described as a predisposing factor to the appearance of associated brain swelling, which is more frequent in subdural hematomas than in epidural hematomas. The interval between the establishment of the coma and the moment of the evacuation surgery is also a clear factor that influences the development of this complication. Early surgery seems to be the only means to prevent the development of associated brain swelling, which is triggered when the intensity and duration of the compressive effect exerted by the hematoma on the underlying cerebral hemisphere exceed a critical level, causing diffuse ischemia and acute edema of the brain tissue. The lesion with the best prognosis is the pure extra-cerebral hematoma. The favorable evolution is easy to predict in those patients operated on an extra-axial hematoma who do not develop associated pathology after surgical evacuation. In them, post-operative ICP is low, as in most patients, and managed medically or surgically (19).

The prognosis of diffuse axonal injury without associated brain swelling is at an intermediate level (4,15). These patients do not present a lucid interval, which indicates that the lesion occurs at the moment of impact, and may show papillary changes without there being herniation of the temporal lobe at the tentorial level. When no mass-occupying mass effect occurs, this lesion does not present with elevation of the ICP, despite which many of these patients remain in a prolonged coma, subsequently developing severe disability or remaining in a persistent vegetative state. Among the epidemiological variables, age is a very influential factor in the evolution of the patient with severe head trauma. In our study, as in others published in the literature, advanced age is associated with a progressive increase in mortality figures. In this sense, it should be noted that mortality in older patients is also related, or is due in part, to the higher incidence of medical complications in this subgroup.

Another clinical fact of great prognostic importance, especially when considered in relation to the type of intracranial lesion, is pupillary changes without there being herniation of the temporal lobe, causing diffuse ischemia and acute edema of the brain tissue. The mechanism causing the serious injury has been revealed as a factor that conditions the final evolution, although this is not always admitted in the different published works. In our study, falls, direct impacts and firearm injuries lead to worse evolution, and within the group of patients who suffer a traffic accident, those with associated systemic lesions have a higher incidence of peri-traumatic hypotension and hypoxemia, with significantly higher mortality. The pattern of behavior of the ICP is of great influence on the final result. Patterns 4 (low / high), 5 (high / low / high) and 6 (high) are associated with 100% mortality. The uncontrolled elevation of the ICP is the most frequent cause of death.

The prognostic value of this variable is modified according to the moment in which it is considered, and thus the pattern of behavior over successive days is more decisive than the initial figures, although these help outline the therapeutic management and guide the prognostic prediction, in the patient suffering from severe head trauma. The need for barbiturate treatment is associated with a less favorable evolution. This is logically related to the patterns of behavior of the ICP, being necessary therapy with Thiopental in those cases with high ICP figures that cannot be managed medically with other measures. The need for decompressive surgery is related to adverse prognosis. It is necessary to consider that this is practiced fundamentally in patients with ICP of difficult control, and who present TC patterns that condition bad prognosis by themselves. In the multivariate study, the pattern of behavior of the ICP, age, pupillary examination, the worst score on the Glasgow Scale, the type of lesions on the control CT, the lesions on the initial CT, and the best score in the Glasgow Scale for the Coma, are the parameters that, in this order, have been more influential in the final evolution of the patient with severe head injury. In the different works collected in the literature, the prognostic reliability of multivariable models ranges between 30% and 45% if applied on the first day, between 53% and 61% if used between the second and third days, and between 53% and 90% if applied between the fourth and seventh days.

Considering, on the one hand, that most deaths occur during the first week, and that as the duration of coma increases, the proportion of patients who remain in a persistent vegetative state or who develop severe disability increases, it is easy to understand importance of prognostic estimates in the early stages of evolution. The number of patients included in our series of severe cranial injury is low, so few parameters acquire significance in multivariable studies and the reliability is not very high. It is expected that as the number of patients increases, new parameters appear in the multivariable models and their reliability increases. In addition, it has been found that the great prognostic capacity of the patterns collected in the CT, the fact of elaborating models similar to the one described for each of the groups in which the patients can be classified according to these patterns, will increase the reliability even more.

CONCLUSIONS

1. Severe head injury is more frequent in males than in females (4/1), predominantly in patients under 35 years of age. The most frequent cause of such mechanism is also the traffic accident (43.1%), followed by the accident of bicycle or motorcycle (22.1%), the fall (17.4%), the outrage (9.3%), the direct impact (2.3%) and the injury by firearm (2.3%).

2. Lesions in severe head injury can be categorized into nine pathological

Neurosurg J Vol 1 No 1 October 2018 11
patterns according to the information provided by the CT. These patterns have a well-defined anatomical and clinical profile and prognostic significance, in turn associated with a pattern of behavior of the characteristic CIP. Pure extra-axial hematomas are the lesions that present the best prognosis, being the diffuse axonal lesion associated with brain swelling and multiple bilateral contusions which lead to worse evolution.

3. The most influential parameters in the final evolution, according to the Bond scale, of the patient with severe head injury are, in this order, the type of behavior pattern of the ICP, age, size and pupillary reactivity, the worst score obtained by the patient in the Glasgow Scale for Coma, the findings in the initial and control CT, and the best score obtained by the patient in the Glasgow Scale for Coma.

4. The Glasgow Coma Scale correctly adjusts to the severity of head injury. The Glasgow Coma Scale is well related to the final prognosis of the patient suffering from severe head injury.

5. The limitation of the study are that all patients being treated in the same hospital, and not a very large sample of patients.
