CASE REPORT

Successful and Integrated Dental Management of Bilateral Ranula in Child: Two Different Approaches for One Case

Clarissa Christina Avelar Fernandez1, Maria Elisa Janini, Lucianne Cople Maia2

Abstract
This paper reports a case of a 10 year old female patient with a chief complaint of swelling in the floor of the mouth. During clinical examination, a large, floating, dome-shaped swelling was observed bilaterally. The probable clinical diagnosis was bilateral ranula. The treatment was performed through oral surgery, in which marsupialization of one injury and enucleation of the other was performed. Histopathological examination revealed extravasated mucin, surrounded by reactive granulation tissue containing foamy histiocytes. Despite the different types of treatment, both ranulas had good prognosis. During dental appointments, there was a significant improvement in oral hygiene. No recurrence was observed over an 18 month follow-up period. An accurate diagnosis and an appropriate treatment plan are fundamental for a successful treatment of ranulas in children. Regardless of the surgical technique, conservative maneuvers associated with careful clinical monitoring were indispensable for the longevity and success of treatment.

Key Words: Ranula, Child, Pediatric Dentistry.

INTRODUCTION
Ranula is a benign oral cystic lesion, infrequent in children, in the floor of the mouth and may extend into the cervical structures (1-3). The treatment depends on the size and location, and is still quite controversial (3). Treatment options can be surgical or not, and includes observation for possible spontaneous regression, aspiration of mucus, marsupialization, enucleation, resection/excision of the lesion and sublingual gland, among others (2-5).

Thus, this case reports a child, with bilateral ranula, in the floor of the mouth and her successful dental management, which includes two different types of treatment, with a rigorous clinical follow-up of 18 months.

CASE REPORT
The patient, a 10 year old female, was referred to the Clinic of Pediatric Dentistry, with a chief complaint of swelling in the floor of the mouth realized 2 months previously.

According to anamnesis, the medical history is not relevant. The extra oral clinical examination showed normality. During the intraoral clinical examination, a large floating, dome-shaped swelling was observed in the floor of the mouth bilaterally, associated with poor oral hygiene and gingival bleeding, was observed (Figure 1). Furthermore, the presence of extended active caries lesions, active white spots and root residual were observed.

Histopathological Examination: Extravasated mucin, surrounded by reactive granulation tissue containing foamy histiocytes (Figure 2). These findings confirmed the initial clinical diagnosis of bilateral ranula.

DISCUSSION
The major and minor salivary glands drain directly into the oral cavity and are responsible for the moisture of the mouth. In the case of obstruction in the outflow of the minor glands and mucus extravasation into tissues, this results in a mucocele. Ranula occurs by the same process, however, is usually associated with the sublingual gland (1). In this report, beyond the relationship with the sublingual gland, the lesion appeared localized in the floor of the mouth, without expansion to the submental and submandibular spaces (4) featuring a simple ranula. Regarding the gender most affected, there is a balance between the accounts in children (3-5), although unilateral

ranulas were more commonly observed (4,5) when compared to bilateral (3). In this case, the patient was a female child with a bilateral lesion, which is more rare and complex to treat.

Clinically, the lesion presents as a floating, homogeneous and well-defined mass on the floor of the mouth (1,2) and the diagnosis is based on these features (2). The initial clinical diagnosis of this report was confirmed by histopathological examination, corroborating other reports (4,5).

According to some authors, a 6 month observation period prior to surgery must be taken into account to assess possible spontaneous regression of the lesion (18.8% of cases, Zhi et al 2008), which may require a different treatment option for children (4). Another study suggests that this period shall not exceed 3 months since there was no spontaneous regression, only increased lesions. In this report, there was no observation period due to the impairment of basic functions of the patient, such as feeding and speech.

The treatments reported in the literature vary according to the type, size and location of the ranula (3-5). Marsupialization is indicated for cases of a simple ranula with a maximum of 2 cm (1,5) and also for cooperative patients (1). The excision of the lesion and the sublingual gland has a low rate of recurrence compared to marsupialization, however, it is considered a radical treatment, and is often restricted to plunging ranulas (1,2,4,5). In these cases, the other glands begin to compensate for the excised gland.

Despite the treatment plan including preventive, restorative and prosthetic dental procedures, its focus was on resolving the main complaint. During surgery, we opted for conservative maneuvers, because these were simple, small ranulas and involved on both sides. Although conservative treatments have higher rates of recurrence (1,2,4,5) no recurrence or complications were observed in this case.

**CONCLUSIONS**

An accurate diagnosis and an appropriate treatment plan are fundamental for a successful treatment of ranulas in children. Regardless of the surgical technique conservative maneuvers associated with careful clinical monitoring were indispensable for the longevity and success of treatment.
